Eutopic and Ectopic Parathyroids in Hyperparathyroidism: Incidence, Localization Trends and Diagnostic Evaluation—Retrospective Data of a Cohort of 400 Patients from a Single Tertiary Institute

Alka A Singhal¹, Deepak Sarin², Ambrish Mithal³, Sanjay S Baijal⁴

Abstract

Aim and objective: To evaluate the incidence of various locations of enlarged eutopic and ectopic parathyroids in patients of hyperparathyroidism, their imaging features, diagnosis, and surgical confirmation. Materials and methods: A retrospective study conducted at a tertiary institution, where 400 patients operated for hyperparathyroidism from 2012 to 2017 was analyzed. Diagnostic findings of Tc-99m-sestamibi scan and ultrasound were compared with surgical findings and subsequent histopathology. Contrast CT(4D CT) was utilized only in select cases. Results: Of 400 patients single adenoma was seen in 350 patients (87.5%), two or more nodules in 41 patients (10.2%), and carcinoma in 3 cases. Of the 350 solitary adenomas, 291 were juxtaposed to thyroid (83.1%), and ectopic in 59 (16.8%) cases. Ectopic along the thymic tract in 38 cases (10.8%), upper mediastinum 8 cases (2.2%), angle of jaw in 2 cases (0.5%), carotid sheath 2 cases (0.5 %), retroesophageal 2 cases (0.5%) and intrathyroidal in 7 cases (2%). Tc-99m-sestamibi scan was positive in localizing parathyroid nodules in 297 (84.8%) cases, and ultrasound in 339 (96.8%) cases. Of the nodules localized by Tc-99m-sestamibi scan, 82% were true and 3% were false localization at the surgery. Nodules localized by ultrasound were true in 99% and false in 1% cases. Ultrasound localized the nodules in sestamibi negative cases in 12% of patients. Conclusion: Identification of enlarged parathyroids and their differentiation from thyroid nodules and other neck lesions is the key role of imaging. Ultrasound is complimentary to Tc-99m-sestamibi scan and offers significant value addition by precision anatomical localization, characterization and finding additional nodules. Using two imaging modalities of Tc-99m-sestamibi scan and ultrasound, the diagnostic sensitivity is 99% and specificity is 98%. Clinical significance: Localization of all the abnormal parathyroid glands in hyperparathyroidism remains a diagnostic challenge on account of both sensitivity and specificity of the available imaging modalities, as well as anatomical variations in the location of the parathyroid glands. A thorough knowledge of the anatomy, embryology along with the merits and pitfalls of the various available imaging modalities is essential to make an accurate preoperative diagnosis and avoid revision surgeries. Keypoints:

• Parathyroid glands are ectopic in 16.8% cases.
• Technetium Tc-99m-sestamibi localizes the parathyroid nodules in 85% cases.
• Ultrasound detects parathyroid nodules in additional sestamibi negative cases (12%).
• Ultrasound gives precise anatomical localization of parathyroid nodules.
• With both MIBI and ultrasound, the diagnostic sensitivity is 99% and specificity is 98%.

Introduction

Localization of the abnormal parathyroid glands in cases of hyperparathyroidism remains a diagnostic challenge both for the nuclear physician and for the radiologist. Various diagnostic modalities are utilized.¹ The usual first-line investigation at our institute is Tc-99m-sestamibi scan, followed by ultrasound. Another cross-sectional imaging, dynamic 4D CT scan was utilized in select cases. The diagnostic dilemma arises both from the anatomical variability in the location of the parathyroids,¹ and the sensitivity of the various available diagnostic modalities. Role of preoperative imaging is very vital in localization of all the abnormal parathyroid glands for effective surgical management.

It allows the surgeon to do a focussed surgery and avoids bilateral neck exploration (BNE). It reduces failed surgeries and revision surgeries.

**Anatomy and Embryology of Parathyroid Glands**

Anatomy and Typical Locations

The parathyroid glands are typically four in number, paired superior and inferior parathyroid glands, although supernumerary parathyroids have also been described with a reported incidence of up to 13%.

Normal parathyroid glands are small and typically measure between 6 mm in length and 3–4 mm in transverse dimensions. The superior parathyroid glands are typically located posterior to the mid part of the thyroid lobe in about 85% cases. The inferior parathyroid glands are typically located within a 1 cm radius along the lower pole of thyroid in majority cases, either inferior, lateral, or posterior to the lower pole or just within the lower capsule of the thyroid gland.

Embryology and Ectopic Locations

The parathyroid glands develop from the endoderm of the third and fourth pharyngeal pouches beginning at the fifth week of embryonic life. Supernumerary parathyroids are very rare, and have been reported in some series to be up to 12.2% in cases of multiple endocrine neoplasia type 1 (MEN1) syndromes. They may lead to failed surgery or persistent hyperparathyroidism (HPT).

Superior Parathyroid Glands

The superior parathyroid glands arise from the endoderm of the fourth pharyngeal pouch. During the sixth week of embryonic development, they descend along with the thyroid, usually in close relation to the posterior aspect of mid thyroid lobe. The typical location of superior parathyroids is just above or within a centimeter radius of the crossing of the inferior thyroid artery and the recurrent laryngeal nerve on the posterior mid surface of the thyroid.

As the superior parathyroids have a smaller descent as compared to inferior parathyroids, they are less likely to show anatomical variability and ectopic locations. The commonest ectopic location of superior parathyroids is behind the upper pole of the thyroid, seen in about 2% cases and rarely beyond and superior to the upper pole in less than 1% cases. Ectopic superior parathyroids may be found in parapharyngeal or parasaophageal, retropharyngeal or retroesophageal locations, or maybe pushed down the tracheoesophageal groove. They may be intrathyroidal in location.

Inferior Parathyroid Glands

The inferior parathyroid glands arise from the endoderm of the third pharyngeal pouch along with the thymus and descend along with them infero-medially towards the upper mediastinum. The inferior parathyroids separate from the thymus before it enters into the mediastinum, and usually localize close to the lower pole of the thyroids. However, any aberration to their separation and descent accounts for the significant anatomical variability in their localization. They could be undescended, overdescended or trapped within the thyroid gland. Ectopic inferior parathyroids may be undescended, located as high up as the angle of the jaw, in the carotid bulb, or overdescended into the superior mediastinum. They may be intrathyrmic or intrathyroidal or be found anywhere along the carotid sheath. An expert and a thorough knowledge of the possible ectopic locations is the key first step in the diagnostic evaluation of the parathyroid glands.

The parathyroid glands show contralateral symmetry of location, with superior parathyroid glands in 80% cases, and inferior parathyroids in only 70% cases.

The superior and inferior parathyroid gland nomenclature is based on the embryologic origin of the parathyroid and not by their level of location in the neck. The inferior parathyroid gland may be located at the same or higher level than the superior parathyroid (in case of undescended ectopic inferior parathyroids).

Supernumerary parathyroids are very rare, and have been reported in some series to be up to 12.2% in cases of multiple endocrine neoplasia type 1 (MEN1) syndromes. They may lead to failed surgery or persistent hyperparathyroidism (HPT).

Materials and Methods

This is a retrospective study performed at a single tertiary institute. Patients operated for hyperparathyroidism from 2012 to 2017 at the institute were analyzed. The sample size was of 400 patients. Diagnostic findings of sestamibi and ultrasound were compared with surgical findings. Single-photon emission computerized tomography (SPECT) was used in select cases.

Results

Of the 400 patients, parathyroid nodules were found in perithyroid locations in 84% cases, and ectopic locations in 16% cases. For the juxtathyroid parathyroids, the sensitivity of localization by ultrasound was 98% and with MIBI Scan was 78%. For the ectopic parathyroids in the neck, the sensitivity of localization by ultrasound was 95% and with sestamibi was 69%. Ultrasound detected additional nodules over those detected by MIBI in 16% cases. Ultrasound localized parathyroid nodules in sestamibi negative HPT in 12% cases. Commonest perithyroid location was right inferior parathyroid. Ectopic locations were as follows; thyrothymic tract 10.8%, angle of jaw 0.5%, tracheoesophageal and periesophageal 0.5%, carotid sheath 0.5%, and intrathyroidal parathyroids 2%. Mediastinal ectopic parathyroid was 1.7%. On histopathology 85.4% were parathyroid adenoma, 11% were parathyroid hyperplasia, and 3.6% were parathyroid carcinoma.

Hyperparathyroidism: Bioclinical Features

An understanding of the serum calcium and parathyroid hormone levels is fundamental to the diagnostic evaluation. Normal serum calcium levels for adults are between 8.4 mg/dL and 10.2 mg/dL. The normal range for adult parathyroid hormone (serum iPTH) levels is 15–68 pg/mL. Levels higher than these values suggest hyperparathyroidism. Correlation with other bioclinical parameters of vitamin D, phosphates and others is done to establish the diagnosis. Mean serum calcium levels noted in this study was 11.9 mg/dL. Mean elevated PTH levels were 360 pg/mL. Very high serum calcium levels (>14 mg/dL) and very high parathyroid hormone levels, in thousands (>4,500 pg/dL) are suspicious of parathyroid carcinoma. Most patients in this study had mild symptoms of weakness or bone/muscle pain. Common associations with renal calculi or pancreatitis were noted.
Tc-99m-sestamibi Scan for Parathyroids

Tc-99m-sestamibi is commonly used to localize parathyroid adenoma either as combined subtraction procedure with 123I or TcO4 or indeed as a sole agent. The radiotracer localizes and is retained in the region of mitochondria. Parathyroid adenoma's high cellularity and vascularity and large number of mitochondria in oxyphil cells are responsible for its avid uptake and slow release.15,16

After IV injection of Tc-99m-sestamibi, initial images are obtained 10–15 minutes after injection which typically show prominent thyroid uptake and a second set of images is obtained at 2–3 hours which showing hyperfunctioning parathyroid gland as a focus of residual activity after much of the thyroid uptake has washed out.17,18 SPECT imaging compared with planar imaging has an advantage in delineating the anatomic localization in some cases. However, no study has shown SPECT to be statistically superior in the sensitivity of detection over planar imaging.19,20

The most common cause for a false-negative study is small size. Sensitivity for detection of second adenomas or four-gland hyperplasia is lower than for single adenomas. Parathyroid tissue expressing P-glycoprotein (P-gp) and/or multidrug resistance-related protein (MRP) also fail to accumulate sestamibi. The most common cause for a false-positive parathyroid study is a thyroid follicular adenoma. Interpretation is also difficult in patients taking thyroxine, where thyroid may not be visualized. Other false-positive images have been described with sarcoidosis, thyroid carcinoma, lymphoma and other tumors.

Ultrasound Features

Typical Parathyroid Nodule

A typical parathyroid nodule appears as a homogeneously hypoechoic ovoid to rounded nodule, other shapes noted have been elongated or bilobed parathyroid. On color Doppler, the parathyroid glands show significantly increased vascularity as compared to the adjacent thyroid along with a characteristic arc rim vascularity noted at one pole. The arc rim vascularity is due to the feeding vessel at one of the poles of the parathyroid nodule, usually along the surface adjacent to the thyroid lobe.21–23 A slight adjustment of the Doppler sensitivity settings may be required to demonstrate the arc and the polar feeding vessel (Figs 1 to 3).

Parathyroid Nodule Size

Parathyroid nodule size may vary from 5 mm to 45 mm or more. The largest longitudinal measurement recorded in our series was 45 mm (Fig. 4). The mean length of the nodule in our series was 18 mm. The measurement of the parathyroid nodules was done in three dimensions and adenoma volume was calculated. These nodule size measurements were compared with histopathology nodule specimen and found to be within ±10% range in 98% cases. Sestamibi negative parathyroid nodules in symptomatic hyperparathyroidism were localized on ultrasound in 12% cases and these measured between 7 mm and 14 mm. Additional or more than one parathyroid nodule were located on ultrasound in 16% cases (Figs 5 and 6).
Eutopic and Ectopic Parathyroids

Figs 2A to D: (A and B) Longitudinal extended field of view in a PHPT patient showing thyroid and a typical inferior parathyroid as a well defined ovoid hypoechoic nodule located just below the lower pole of the thyroid; (C and D) Color Doppler images showing the characteristic feeding vessel entering at one of the poles of the parathyroid nodule.

Figs 3A and B: (A) Tc-99m-sestamibi scan for parathyroids in a PHPT patient showing a large right superior parathyroid adenoma as an area of retention of technetium in the right upper neck on the delayed images; (B) Longitudinal ultrasound image showing a large bilobed parathyroid measuring 35 mm × 15 mm, located just behind the upper pole of right thyroid.

Figs 4A to C: (A) Tc-99m-sestamibi scan for parathyroids in a PHPT patient showing an area of retention of technetium in the right side neck all along with the right lobe thyroid; (B) Longitudinal ultrasound image showing a large elongated parathyroid measuring 45 mm × 15 mm, located behind the whole of right lobe thyroid. The thyroid was small and displaced medially; (C) Color Doppler showing the characteristic arc rim vascularity in the parathyroid nodule.
Atypical Parathyroid Nodules on Ultrasound

Parathyroid nodules may show cystic changes and calcifications. The cystic changes may be a small cystic area or larger cystic area with small solid soft tissue component in cases of large parathyroid adenomas. Rarely, few thin septations may be seen (Fig. 7). The cystic change is significant from the aspect of the diagnostic evaluation, as on sestamibi only the solid component will show tracer uptake, and the true extent of the size of the lesion can be underestimated (Figs 8 and 9). Ultrasound evaluation is a very valuable adjunct here.

Parathyroid Carcinoma

Parathyroid carcinoma as a cause of hyperparathyroidism may be suspected clinically when the elevated serum calcium, serum PTH, (often serum calcium is elevated to more than (>14 mg/dL) and serum PTH elevated to more than (>4,500 pg/dL)) and the clinical symptoms are more severe. It may be associated with genetic syndromes as MEN1. Often when not suspected clinically, ultrasound imaging findings may be the only preoperative clue whether the lesion is likely to be a benign parathyroid adenoma or a parathyroid carcinoma. On ultrasound, parathyroid carcinoma lesion is more heterogeneous and more hypoechoic, it may show heterogeneous vascularity. Its margins with the adjacent thyroid may not be delineated (Fig. 10). It is important to recognize these features as accordingly the preoperative counseling and surgical management changes from minimally invasive parathyroidectomy to an added thyroidectomy or more extensive en bloc surgery.

Parathyroid Cysts

Parathyroid cysts are rare and usually appear as small clear cysts. They may or may not be functional. Diagnosis is confirmed by histopathology.
Figs 7A to D: Ultrasound images of atypical parathyroid nodules: (A) Heterogeneous hypoechoic nodule; (B) Parathyroid nodule with enhancing septa; (C) Parathyroid nodule with small cystic change; (D) Parathyroid nodule with multiple cystic changes. Post-surgery histopathology of all the four nodules is parathyroid adenoma.

Figs 8A to C: Ultrasound images of parathyroid nodules with large cystic change: (A) Parathyroid nodule with a large cystic change in the central part; (B) Parathyroid nodule with only a small solid soft tissue area in its upper part and a large cystic component dipping deep into the posterior neck; (C) Parathyroid nodule with a large cystic change in the upper part and a small soft tissue component in the lower part. Post-surgery histopathology of all the four nodules was parathyroid adenoma.
Eutopic and Ectopic Parathyroids

Ectopic parathyroid locations noted were as follows: 19,20 thyrothymic tract 10.8%, angle of jaw 0.5%, tracheoesophageal and paraesophageal 0.5%, carotid sheath 0.5%, and intrathyroidal parathyroids 2%. Mediastinal ectopic parathyroid was 1.7%. On histopathology, 85.4% were parathyroid adenoma, 11% were parathyroid hyperplasia and 3.6% were parathyroid carcinoma.

Undescended Parathyroid

The parathyroids originate from the endoderm of the third and fourth pharyngeal pouch, superior from IV, and inferior from the III, and descend along with the thyroid and thymus to their usual perithyroid locations. An undescended parathyroid4 may result as a failure of descent and are usually located at the angle of jaw, just lateral to the submandibular gland (Fig. 11C).

Ectopic along the Thymothymic Tract

This is the commonest location of the ectopic parathyroids and it usually results in failure of separation of the inferior parathyroids from the thymus during their descent and they may be carried inferioiy beyond the lower pole of the thyroid to up to superior mediastinum. Ectopic inferior parathyroids located up to the angle of manubrium sterni are amenable to visualization by ultrasound.
If required a high frequency transducer with a very small footprint such as the hockey stick probe may be utilized to maneuver along the trachea and tracheoesophageal groove.

**Ectopic Parathyroid in Carotid Sheath**

Ectopic parathyroids in the carotid sheath are rare, and a thorough transverse and longitudinal scan along the common carotid artery and its bifurcation are required to identify these. Color Doppler settings must be appropriate to elicit the characteristic findings, which could otherwise be masked by the carotid vessel itself (Fig. 12).

**Ectopic in Tracheoesophageal/Paraesophageal Groove**

These ectopic parathyroids are located slightly deviated from their path, often laterally and posteriorly are a challenge in diagnosis. The commonest differential diagnosis is from a lymph node in the area of tracheoesophageal or paraesophageal groove. Correlation with another imaging modality, usually Tc-99m-sestamibi or contrast CT neck is required to establish a definite preoperative diagnosis (Figs 13A and B).

**Intrathyroidal Parathyroids**

Intrathyroidal parathyroids are one of the rare locations of ectopic parathyroids and result when the parathyroid glands get trapped in the thyroid during descent.

On MIBI scan there may be a focal area of increased uptake in the thyroid gland, which could be due to parathyroid adenoma or a follicular adenoma. Both follicular adenoma and parathyroid nodules may show increased vascularity and pose a diagnostic challenge in differentiation. When seen, the characteristic arc
rim vascularity is highly suggestive of the parathyroid glands.21 Another cross-sectional modality such as a dynamic CT Scan may be utilized in difficult cases. True intrathyroidal parathyroids show parathyroid tissue embedded in thyroid tissue on histopathology (Figs 13C and D).

Ectopic Mediastinal Parathyroids
Parathyroids may be overdescended and reach the mediastinum,24,25 and by definition are located below the level of clavicles. Ectopic inferior parathyroids move with the thymus and are usually seen in the anterior mediastinum. Ectopic superior parathyroids are usually located in the posterosuperior mediastinum. These may be localized by the sestamibi scan as an area of focal tracer retention in the mediastinum on delayed images (Fig. 14). CT scan is required in these cases for localization.

Conclusion
Localization of parathyroid adenoma in cases of hyperparathyroidism still remains a diagnostic challenge. Significant anatomical variations and the possibility of supernumerary parathyroids must be remembered. Along with the sestamibi scan, another cross-sectional modality must be utilized, either an ultrasound or a CT scan before surgery. An attempt must be made to localize all the four parathyroid glands, over and above the sestamibi findings. An accurate preoperative localization will allow for more focused Parathyroidectomies and reduce the need for BNE and revision surgeries.
